1 Introduction

Moved to the GitHub repository `codatomrc/tesi`.

2 Background spectrum extraction

2.1 Automatic detection

- Explore the working directory to find all the raw files automatically.
- Integrate over all the wavelenghts by summing the data in the dispersion direction. In this way a can synthetically see the flux along the spatial direction, regardless the source (i.e. continuum or line).
- Detect the amplitude of the noise by comparing the luminosity profile with a de-trended one. For de-trending I used a biweighted algorithm with a windows size of 10 times the slit size. I used the function `wotam.flatten`.

  I also estimated the average bkg level as the average value of the de-trended profile. The choice of a large window allows to smear out the signal of the peaks providing a good estimation of the actual bkg level.
- Detect the peaks the integrated flux using the function `scipy.signal.find_peaks`. This function finds the local maxima of an 1D signal.

  On the current data it was convenient to filter the detected peak to have a prominence equal to the estimated bkg noise amplitude. I also restricted the research to peaks with a witdth larger than 3 px which prevents cosmic rays to be recorded as astronomical sources. On the current configuration cosmic rays produes traces that spans about 3-5 px on the dispersion direction while 1-2 px on the spatial direction.
- Measure the width of each peak with `scipy.signal.peak_widths`. This function is designed to work with noisy signal and several maxima and minima, instead of just some maxima above a flat background. I set the option `rel_height=0.5` to measure the FWHM of each peack instead of the width at the base, which turned to be not very solid for the data we had.
- Mask the regions around the peaks. After some testing, the best strated (with the data available) is to remove a region of width 3× FWHM around each peak. Such whide span is necessary since many sources present a luminosity profile with a bright core and extended wings.
- Extract the data of the background as those outside the region of the peaks. These are the areas that will be used for the analysis.

Note that due to the variety of luminosity profiles of astronomical sources it is not very efficient to develope a qualitative approach to compute the best width. This empirical treatment is good enough (if it will prove to be solid with more data though).

A quantitative approach. I tried to sketch a qualitative model where I assumed gaussian profiles of the sources. The source ended when its flux was comparable to the amplitude of the bkg noise. The final distance Δ from the center of the source was

$$\Delta = \frac{1}{2\sqrt{2\ln 2}}\mathrm{FWHM}\sqrt{\ln(S_{\max}^2/B)}$$

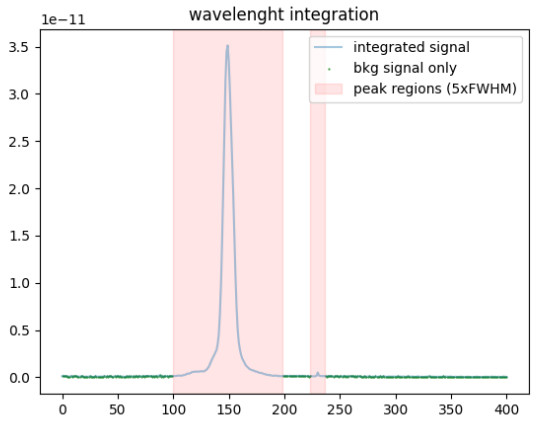
where $S_{\max}$ was the maximum counts of the source, while B the average level of bkg around the object. Since many extended objects cannot be reproduced by gaussian profiles this estimation may be misleading in many cases. Since the empirical procedure discussed above seems quite solid with current data, implementing a rigorous analytical approach that accounts for different luminosity profiles of the sources, is definitively unecessary.

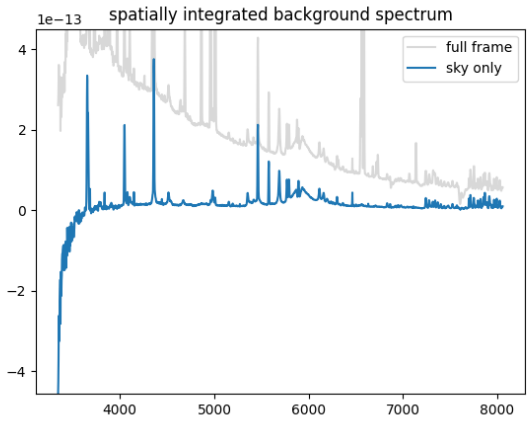
2.2 Preliminary results

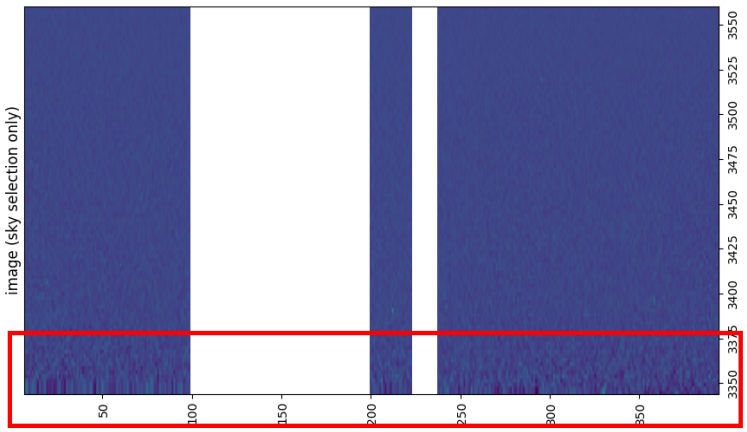
Here the results with the two frames available.

All the data. Wavelenght integrated profiles and bkg-removed spectra obtained with the current configuration are available in the directories `plots/integr` and `plots/sky_spec` resepctively. The masked spectra are saved in the same directories of the original files with synthax `filename.fc.bkg.fits`.

NGC2392 (2006/ima_010). The Eskimo Nebula. There is a sharp peak with strong wings. Probably another very faint source is present in the field. The script does recognize both the signals and removes them.







We integrate over all the position along the slit where we no astronomical sources/signals are present. Then we plot it against the wavelenght to obtain the spectrum of the background (atmospheric emission + light pollution).

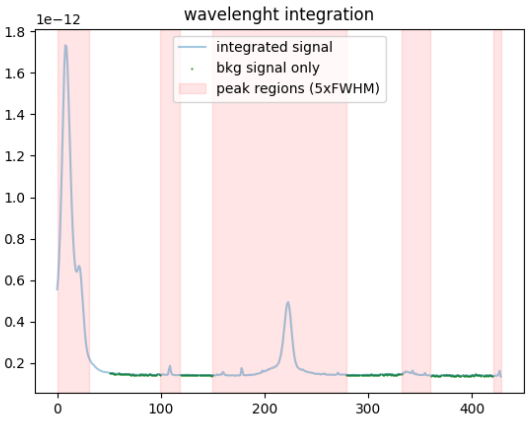
In the removal they comes out negative fluxes in the bluer hand of the spectrum. We realize that the wavelenght range in this frame begins at $\sim 3344\,\text{Å}$ which considerable as UV radiation. It is not so surprising to find inaccurate results at those extreme wavelenghts.

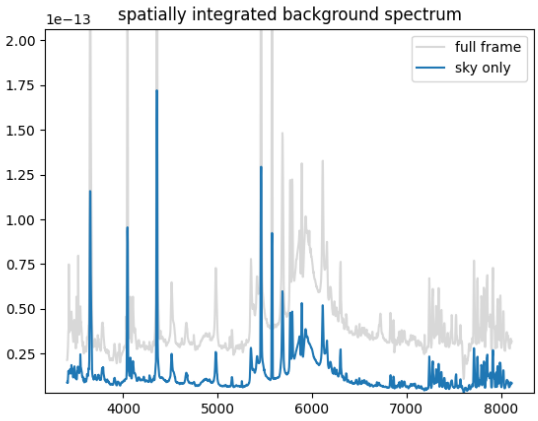
Ark564 (2006/ima_015). In this case the sources along the slit seems to be several but the script seems to be able to manage all of them. In this case the spectrum of the background do not seem to present any issue.

2.3 Comments on the first results

Cosmic rays removal. Many of the peaks in the integrated luminosity profiles have a widths lower than 4 px, i.e. are very likely to be cosmic rays. These traces must be actually identified and removed from the final masked file with the bkg spectrum.

Wavelenght limitations. It would be convenient to set a wavelenght treshold for the analized data. Wavelenghts outside the spectrograph+telescope working range may led to biased measurements.





Frame limitations(?) I wonder wether the whole CCD area is suitable for collecting data or it would be better/necessary to neglect some specific regions, both in the spatial and dispersion directions.

What about the lines "`CCDSEC`" and "`BIASSEC`" in the header of the frames?

3 Appendix: Python source code

The code I am using.

```
